An Efficient C Language Based Message Passing Codec for LDPC Sheng Xu U5538588

Supervised by Dr. Gerard Borg

October 2016

A thesis submitted in part fulfilment of the degree of
Bachelor of Engineering
Department of Engineering
Australian National University

This thesis contains no material which has been accepted for the award of any other degree or diploma in any university. To the best of the author's knowledge, it contains no material previously published or written by another person, except where due reference is made in the text. Sheng Xu 31 October 2016 © Sheng Xu

Acknowledgements

The research experience for the honours project is a memorable and meaningful memory in my academic career. Since many peoples have kindly shared their creative ideas and support to me, it is hard to name everyone who has helped me during the academic year. However, there are some respectable persons whom I would like to express my gratitude to. Firstly, I faithfully thank my supervisor, Dr. Gerard Borg. Whenever I was confused by certain basic or demanding questions, he has always shown his great patience to me with introducing all the associated knowledge until I finally understand the context. Secondly, I thank the alumnus, Mr. Sang Ik Park. Although we have never met with each other, his code and work notes of the previous honours project did have provided a host of helpful and valuable ideas to me so that I could have boosted the practical performance of my decoder. Thirdly, I thank my team members of the course Engineering Innovation and Systems Engineering Project. Thanks for their understanding and tolerance, I am able to put the most time and efforts on this project during the busy semesters.

All in all, I have so many peoples to thank. Lastly, I thank my family and friends who have expressed their greatest respect and faith to me so that I could focus on this project during this academic year.

ABSTRACT

The term Low-Density Parity Check code was firstly introduced by Dr. Gallager in the year 1963 and reinvented by Mackay and Neal in 1996 (Mackay and Neal's decoding algorithm). This particular code has contributed extraordinarily to many peoples' research works and has been utilized in a diverse range of applications in the signal processing domain. One of the applications is the Digital Video Broadcasting – Satellite generation 2 (DVB-S2).

In this thesis, the basic knowledge of the encoding process and decoding process are firstly introduced. Additionally, the currently used DVB-S2 standard encoding algorithm is explained in detail. Furthermore, four types of message - passing decoding algorithms (Erasure decoding, Bit-flipping decoding, Sum-product decoding and Mackay and Neal's decoding algorithms) are detailed illustrated.

Next, the first attempt on implementing a low-complex encoding algorithm is demonstrated with detailed coding procedures provided. What's more, the realized MN decoder of the Mackay and Neal's decoding algorithm is also fully interpreted.

Apart from these, the comparison of the practical decoding performance of the Sumproduct decoder and the new constructed MN decoder will be shown with detailed analysis provided.

In addition to the conclusion, the future development of the decoder is also suggested so that those who might use this thesis as a reference for their academic research could obtain some valuable ideas.

1. Introduction

1.1 An Efficient C Language Based Message Passing Codec for LDPC

Along with the growth of the living standard and disposable income of the public, the demand for accurate and fast signal transmission technology is increasing. In the field of audiovisual experience, a systematic standard named Second Generation of Digital Video Broadcasting – Satellite (DVBS2, 2012) is widely applied to digital television system in many countries, such as the USA, Canada, Greenland, Saint Pierre and Miquelon and etc. (SRG SSR, 2016) due to its wide coverage and the large capacity of the programs. Furthermore, its theoretical transmitting data rate can reach up to 10Mb/s (Satellite end DVB, 2016), which realizes the simultaneously using of multi-programs while keeping the high quality of audiovisual experience.

When it comes to the domain of signal transmission, messages are firstly transmitted in the form of strings which consist of binary values '0's and '1's (Sarah Johnson, 2006). Then, based on the ASCII standard code, messages will be converted to corresponding characters and symbols, and finally represented to receivers. However, in the real world, there are a host of noise signals which can negatively affect the original message sent from the transmitter (such as randomly add a series of decimals to the bit values) and consequently cause the inaccurate data received at the receiver. Therefore, the method of automatic error detection and correction should be of great concern to the signal processing stage at the receiver.

In 1962, the term Low-density parity-check (LDPC) code was first introduced by doctor Gallager at MIT (Robert G. Gallager, 1963). It is a block code with a parity-check matrix which has only a small quantity of '1's inside. Hence, the complexity of encoding and decoding process can be reduced by the sparseness of the matrix.

Up to now, a diverse range of the methods for constructing LDPC code have been introduced by many researchers. Such as Gallager's parity-check matrices, constructing method

proposed by MacKay and Neal (MacKay and Neal, 1996), decoding algorithm introduced by Gottfried Lechner and Jossy Sayiretc (Gottfried Lechner and Jossy Sayir, 2004), etc. Although these methods were recognized as effective and efficient, the performance of the methods might be lower than expectations after constructing the methods in practice.

This project – An Efficient C Language Based Message Passing Codec for LDPC - aims to address the most efficient and feasible codec and seek for further improvement by comparing the actual performances after C programming. Previous research works on LDPC were used as references throughout the compiling and debugging stages.

Procedure of this project:

- Chose the most feasible method for implementing the codec from the existing theses.
- Construct the codec in C platform and test the processing speed.
- Compare the performance with the currently used code.
- Seek for further acceleration on the processing time of error detection and correction.

1.2 Outline

Theory

Briefly introduce the encoding and decoding process with correlated symbols and their relationships described.

DVB-S2 standard encoding algorithm is demonstrated in detail.

The comparison of different message-passing decoding algorithms is introduced.

The theories of existing decoder and new decoder are introduced in detail.

Methodology

The methodology of implementing theoretical algorithms in C is fully described.

The methods of improving the performance and feasibility are described in detail.

Result and Discussion

Practical performance of the decoder is analyzed.

Results from the sum-product decoder and the new decoder are fully compared and analyzed.

Conclusion and Future Development

The project is briefly summarized. The review of the outcomes and the suggestions of future development are provided.

2. Theory Background

In the domain of signal processing, signals are firstly converted to binary sequences before being transmitted. In other words, each transmitted message is actually a sequence of binary number '1's and '0's. To begin with, it is necessary to introduce the relationships of original message **u**, encoded codeword **c**, received codeword **r** and decoded codeword **y**.

2.1 Brief introduction of encoding process

In the transmitter terminal, the original message \mathbf{u} - which contains \mathbf{k} message bits - is firstly encoded to codeword \mathbf{c} based on the module-2 additive equation $\mathbf{c} = \mathbf{u}\mathbf{G}$ (where \mathbf{G} is the generator matrix of the code in the size of $\mathbf{k} * \mathbf{n}$ and \mathbf{n} is the code length of the encoded codeword \mathbf{c}). The form of the matrix \mathbf{G} can be separated into two parts: a $\mathbf{k} * \mathbf{k}$ identity matrix $\mathbf{I}_{\mathbf{k}}$ and the following matrix \mathbf{A} in the size of $\mathbf{k} * (\mathbf{n} - \mathbf{k})$. That is the form of matrix \mathbf{G} is $[\mathbf{I}_{\mathbf{k}}, \mathbf{A}_{\mathbf{k}*(\mathbf{n} - \mathbf{k})}]$. Therefore, the first \mathbf{k} bits of the encoded codeword \mathbf{c} are exactly the same as the bits of the original codeword \mathbf{u} after encoding process. Additionally, the remaining $\mathbf{n} - \mathbf{k}$ bits of \mathbf{c} will be the parity check bits.

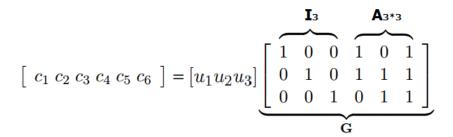

Figure 2.1: Encoding Algorithm with k = 3 and n = 6

2.2 Brief introduction of LDPC decoding process

In the ideal case, the received message codeword \mathbf{r} in the receiver should always be the same as the encoded codeword \mathbf{c} sent from the transmitter. However, in the real world, errors could occur during the transmission and so the parity- checks become useful to detect whether the error happens during the transmission.

For a received codeword $\mathbf{r} = [\mathbf{r}_1 \ \mathbf{r}_2 \ \mathbf{r}_3 \ \mathbf{r}_4 \ \mathbf{r}_5 \ \mathbf{r}_6 \ \mathbf{r}_7 \ \mathbf{r}_8]$, the bits should always satisfy the following parity-check equation:

$$r_1 \oplus r_2 \oplus r_3 \oplus r_4 \oplus r_5 \oplus r_6 \oplus r_7 \oplus r_8 = 0$$
;

Where each bit r_i is either '1' or '0' and \oplus means modulo-2 addition.

If the result is '1', then at least one error has occurred during the transmission.

However, parity-check equations can only check the occurring of errors without indicating which bits are wrong. Furthermore, errors can only be detected but not able to be corrected by only applying a single parity-check equation. Therefore, parity-check matrix **H** comes in handy.

The matrix \mathbf{H} is actually the orthogonal matrix of \mathbf{G} , that is the matrices \mathbf{H} and \mathbf{G} should satisfy that $\mathbf{G}\mathbf{H}^T=0$. As it was mentioned in the previous section, for a length \mathbf{k} codeword \mathbf{u} and its encoded codeword with a length of \mathbf{n} , the size of generator matrix \mathbf{G} should be $\mathbf{k} * \mathbf{n}$ and in the form $\mathbf{G}=[\mathbf{I}_{\mathbf{k}},\mathbf{A}_{\mathbf{k}^*(\mathbf{n}-\mathbf{k})}]$. Therefore, the size of \mathbf{H} should be $(\mathbf{n}-\mathbf{k})*\mathbf{n}$ (n-k check nodes and n bit nodes), and the form of \mathbf{H} is supposed to be $\mathbf{H}=[\mathbf{A}^T,\mathbf{I}_{\mathbf{n}-\mathbf{k}}]$

Example 2.2: —

$$\mathbf{r} = [\mathbf{r}_1 \ \mathbf{r}_2 \ \mathbf{r}_3 \ \mathbf{r}_4 \ \mathbf{r}_5 \ \mathbf{r}_6], \quad \mathbf{H} = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 \end{bmatrix}$$

$$\mathbf{s} = \mathbf{H}\mathbf{r}^{\mathbf{T}} = \underbrace{\left[\begin{array}{ccccc} 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 \end{array}\right]}_{H} \begin{bmatrix} \mathbf{r}_{1} \\ \mathbf{r}_{2} \\ \mathbf{r}_{3} \\ \mathbf{r}_{4} \\ \mathbf{r}_{5} \\ \mathbf{r}_{6} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_{1} \oplus \mathbf{r}_{2} \oplus \mathbf{r}_{4} \\ \mathbf{r}_{2} \oplus \mathbf{r}_{3} \oplus \mathbf{r}_{5} \\ \mathbf{r}_{1} \oplus \mathbf{r}_{2} \oplus \mathbf{r}_{3} \oplus \mathbf{r}_{6} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

As shown in example 2.2, in the parity-check matrix \mathbf{H} , each row represents a parity-check equation and each column of \mathbf{H} indicates one bit in the codeword. So, if a received codeword \mathbf{r} and its parity-check matrix \mathbf{H} are known in advance, the codeword is valid only if: $\mathbf{s} = \mathbf{H}\mathbf{r}^{\mathbf{T}} = 0$, where $\mathbf{r}^{\mathbf{T}}$ is the transpose matrix of the codeword \mathbf{r} and \mathbf{s} is the syndrome of the codeword \mathbf{r} . In the example, since all the three parity check equations equal to '0', the received codeword \mathbf{r} is valid. Hence, the first \mathbf{k} bits of \mathbf{r} will be extracted as the decoded codeword \mathbf{y} , which should be exactly the same as the original message \mathbf{u} . If any one of the equations equals to '1', then the error can be located in the correlated bits of the corresponding equation.

2.3 DVB-S2 standard encoding algorithm

Theoretically, the parity check bits should be the last \mathbf{n} - \mathbf{k} bits of the codeword \mathbf{c} , which were calculated from the equation $\mathbf{c} = \mathbf{u}\mathbf{G}$. However, unlike the programming languages such as Matlab, which was generated for operating the matrix related calculation, C programming performs poorly in handling with the calculations of matrix. In other words, building a generator matrix with the size of 7200 x 16200 is extremely time-consuming and kind of wasting memory resource. Nevertheless, if 2D matrices can be converted to 1D vectors, the speed of operating algorithmic calculations will be sharply accelerated. Fortunately, the European Standard inner encoding algorithm (EBU-UER, 2009) has introduced the method to address the problem. In this thesis, the algorithm for 16200 coded block with half rate is demonstrated as the example.

As mentioned in previous sections, in the encoded codeword \mathbf{c} which has the length of \mathbf{n} =16200, the first $\mathbf{k}=7200$ bits are exactly the same as the original message \mathbf{u} , and the remaining \mathbf{n} - $\mathbf{k}=9000$ bits are the parity check bits (\mathbf{p}_0 , \mathbf{p}_1 , ..., \mathbf{p}_{8999}) of the codeword. That is $\mathbf{c}=(\mathbf{u}_0,\mathbf{u}_1,\ldots,\mathbf{u}_{7198},\mathbf{u}_{7199},\mathbf{p}_0,\mathbf{p}_1,\ldots,\mathbf{p}_{8999})$. Since the bits of original message \mathbf{u} have been stored in the memory locations of the transmitter, the parity check bits can be acquired from the information bits \mathbf{u}_i (where $i \in (0,7199)$) at the designated addresses in the i^{th} line of the table shown in Appendix A. Detailed procedures are shown as follow:

- Initially, all parity check bits are reset to '0'.
- Then update the specified bits shown in the 1st row of the table in Appendix A:

$$p_{20} = p_{20} \oplus u_0, \qquad p_{712} = p_{712} \oplus u_0,$$

$$p_{2386} = p_{2386} \oplus u_0, \qquad p_{6354} = p_{6354} \oplus u_0,$$

$$p_{4061} = p_{4061} \oplus u_0, \qquad p_{1062} = p_{1062} \oplus u_0,$$

$$p_{5045} = p_{5045} \oplus u_0, \qquad p_{5158} = p_{5158} \oplus u_0,$$

 Similarly, update the specified bits shown in the second row of the table in Appendix A:

$$\begin{array}{lll} p_{45} = p_{45} \oplus u_1, & p_{737} = p_{737} \oplus u_1, \\ \\ p_{2411} = p_{2411} \oplus u_1, & p_{6379} = p_{6379} \oplus u_1, \\ \\ p_{4086} = p_{4086} \oplus u_1, & p_{1087} = p_{1087} \oplus u_1, \\ \\ p_{5070} = p_{5070} \oplus u_1, & p_{5183} = p_{5183} \oplus u_1, \end{array}$$

- Repeat the procedure for each following row until reaching the row 1800.
- For the row 1801, update the specified bits shown in Appendix A:

$$p_0 = p_0 \, \oplus \, u_{1800}, \quad p_{4046} = p_{4046} \, \oplus \, u_{1800}, \quad p_{6934} = p_{6934} \, \oplus \, u_{1800}$$

• Repeat above procedure for the remaining rows until the end of the table.

Once all the parity check bits are refreshed, the encoded codeword \mathbf{c} with the length of 16200(7200+9000) can be obtained from:

$$\mathbf{c} = (\mathbf{u}_0, \, \mathbf{u}_1, \, \dots, \, \mathbf{u}_{7198}, \, \mathbf{u}_{7199}, \, \mathbf{p}_0, \, \mathbf{p}_1, \, \dots, \, \mathbf{p}_{8998}, \, \mathbf{p}_{8999})$$

Practical results showed that the efficiency of the way for encoding the original message codeword is significantly higher than that of generating the encoded codeword directly from the pre-constructed generator matrix. Detailed discussion and analyzing will be shown in section 3.

2.4 Algorithms of Message- Passing Decoder

In this section, four message passing decoding algorithms (Erasure Decoding, Bit-Flipping Decoding, Sum-Product Decoding and Mackay and Neal's Decoding algorithms) are introduced on the theoretical level. In addition, reasonable justifications for the final choice of the implemented decoding algorithm are also provided.

2.4.1 Erasure Decoding

According to previous sections, in a parity check matrix \mathbf{H} , each row represents a single parity check equation and the value of each bit in the equation is either '1' or '0'. In order to simplify the decoding process and save the memory resources, only the column indexes of '1's in a parity check equation are necessary to be recorded in a new vector \mathbf{B}_i , where 'i' indicates the index of the parity check equation in the matrix \mathbf{H} . Therefore, if there is at least one parity check equation which contains only one unknown bit while other bit-values are known, the value of the unknown bit can be estimated by applying the module-2 addition on the known bits in the same parity check equation. Detailed procedures can be shown in the following example.

Example 2.4.1 _____

After transmitting through an erasure channel, the encoded codeword $\mathbf{c} = [0\ 0\ 1\ 0\ 1\ 1]$ was received as $\mathbf{r} = [0\ 0\ 1\ x\ x\ x]$.

Given that the parity check matrix **H** for the code is known as:
$$H = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix}$$

Then the vectors which include the positions of '1's in each row can be obtained as:

$$B_1 = \{1, 2, 4\}$$
 $B_2 = \{2, 3, 5\}$ $B_3 = \{1, 5, 6\}$ $B_4 = \{3, 4, 6\}$

So from B_1 : $\mathbf{r}_4 = \mathbf{r}_1 \oplus \mathbf{r}_2 = 0 \oplus 0 = 0$;

Similarly, from B₂: $\mathbf{r}_5 = \mathbf{r}_2 \oplus \mathbf{r}_3 = 0 \oplus 1 = 1$;

Since \mathbf{v}_4 is known now, the value of \mathbf{v}_6 can be obtained from \mathbf{B}_4 :

$$\mathbf{r}_6 = \mathbf{r}_3 \oplus \mathbf{r}_4 = 1 \oplus 0 = 1.$$

Therefore, the recovered codeword is:

$$\mathbf{r} = [0\ 0\ 1\ 0\ 1\ 1]$$

which is the same as the transmited codeword

$$\mathbf{c} = [0\ 0\ 1\ 0\ 1\ 1].$$

The erasure decoding provides a simplest but efficient way to recover the erased bits. However, if none of the parity check equations contains only one unknown bit-value, the transmitted codeword might not be fully recovered. Moreover, since the noise signals are randomly added to the transmitted signal, it is not able to ensure that there always exists a parity check equation which contains only one unknown bit. Therefore, this algorithm can not be used for the message passing decoder of DVB-S2.

2.4.2 Bit-Flipping Decoding

The algorithm Bit-Flipping Decoding is similar to Erasure Decoding process. The only difference is that in addition to using the sets of bits \mathbf{B}_i only, each received bit-value also contributes to determining the final value of the codeword. To be brief, majority rule is the second step of bit correction. Detailed decoding procedures are shown in the following example.

Recall example 2.4.1: The encoded codeword is $\mathbf{c} = [0\ 0\ 1\ 0\ 1\ 1]$ and now the received codeword becomes to $\mathbf{r} = [1\ 0\ 1\ 0\ 1\ 1]$ (after traveling through a BSC channel with crossover probability: p = 0.2).

From the parity check matrix **H**:

$$B_1 = \{1, 2, 4\}$$
 $B_2 = \{2, 3, 5\}$ $B_3 = \{1, 5, 6\}$ $B_4 = \{3, 4, 6\}$

Firstly, similar calculation procedures shown in example 2.4.1 are applied to calculate values of the bits in each parity check equation 'B_i'. Calculating results can be shown in the following table:

Table 2.4.2: Bit values calculated from each parity check equation

Bit Value	\mathbf{r}_1	\mathbf{r}_2	r ₃	r 4	r ₅	\mathbf{r}_6
Resource						
B ₁ suggested	0	1		1		
B ₂ suggested		0	1		1	
B ₃ suggested	0				0	0
B ₄ suggested			1	0		1
Received	1	0	1	0	1	1

Secondly, count the number of '1's and '0's in each column and then take the dominant value as the final value of the corresponding bit.

So, for bit \mathbf{r}_1 , 2/3 of the results suggested that the value should be '0' rather than '1'. Therefore, \mathbf{r}_1 is refreshed to '0';

For bit \mathbf{r}_2 , 2/3 of the results suggested that bit value of \mathbf{r}_2 should remain '0' and so \mathbf{r}_2 remains unchanged ($\mathbf{r}_2 = 0$ ').

Consequently, the corrected codeword is: $\mathbf{r} = [0\ 0\ 1\ 0\ 1\ 1]$, which is the same as the transmitted value $\mathbf{c} = [0\ 0\ 1\ 0\ 1\ 1]$.

In order to verify whether the corrected bit-values are valid, parity check vectors ranging from ${\bf B}_1$ to ${\bf B}_4$ are applied on the refreshed codeword ${\bf r}$:

From
$$\mathbf{B}_1$$
: $\mathbf{r}_1 \oplus \mathbf{r}_2 \oplus \mathbf{r}_4 = 0 \oplus 0 \oplus 0 = 0$ (Valid);

From **B**₂:
$$\mathbf{r}_2 \oplus \mathbf{r}_3 \oplus \mathbf{r}_5 = 0 \oplus 1 \oplus 1 = 0$$
 (Valid);

From **B**₃:
$$\mathbf{r}_1 \oplus \mathbf{r}_5 \oplus \mathbf{r}_6 = 0 \oplus 1 \oplus 1 = 0$$
 (Valid);

From
$$\mathbf{B}_1$$
: $\mathbf{r}_3 \oplus \mathbf{r}_4 \oplus \mathbf{r}_6 = 1 \oplus 0 \oplus 1 = 0$ (Valid);

Since all the parity check equations are satisfied, the decoding algorithm completes. Otherwise, algorithm should repeat until the final codeword is valid.

Obviously, the bit-flipping algorithm further improved the decoding performance of the erasure decoding algorithm. Error bit-values can be detected and corrected even if more than 1 errors existing in the codeword. However, if there are two or more bits involved in the same parity-check equations, the system would not able to locate the error bit accurately. Similarly, considering that the noise signals are randomly added to the transmitted codeword in the real case, this algorithm is not taken into account for the message passing decoder of DVB-S2.

2.4.3 Sum-Product Decoding

Unlike the previous decoding algorithms, Sum-Product algorithm is a soft decision message passing algorithm (Sarah Johnson, 2006). Which means that rather than received bits themselves, the probabilities of bit-values are utilized as the inputs of the algorithm.

As is was mentioned in previous sections, in the signal transmission domain, message bits are transmitted as binary values '0's or '1's. Therefore, for the value of a single codeword bit, there always exists a relationship between the likelihood that the value of bit \mathbf{x} is '1' and the likelihood that the value of the same bit is '0': $p(\mathbf{x}=1) = 1 - p(\mathbf{x}=0)$. So, the log likelihood ratio (LLR) for bit \mathbf{x} can be represented as: $LLR(\mathbf{x}) = \log (p(\mathbf{x}=0) / p(\mathbf{x}=1))$. Obviously, if the probability of $\mathbf{x} = 0$ is larger than that of $\mathbf{x} = 1$, the value of the variable $LLR(\mathbf{x})$ would be positive; In contrast, if the probability of $\mathbf{x} = 0$ is smaller than that of $\mathbf{x} = 1$, the value of $LLR(\mathbf{x})$ would be negative. Furthermore, the greater that the absolute value of $LLR(\mathbf{x})$ is, the more reliable that the suggested bit-value will be.

In fact, the Sum-product decoding algorithm is similar to the Bit-flipping algorithm. As each column in the parity check matrix **H** is actually the index of the corresponding codeword bit which participating in certain parity check equations, the Sum-product algorithm firstly calculates the log likelihood value of each codeword bit and assigns this probability to the positions of '1's in the corresponding column of a temporary matrix (which has the same size of **H**); then figures out the signed product of these elements to obtain the overall probability by iteratively applying the associated parity check equations. After combining the likelihood

product and the log likelihood value of the bit (calculate the sum of the two results), the final sum-product probability of the bit can be worked out. Therefore, if the probability value is positive, the bit value will be refreshed to '0'; Otherwise, it will be refreshed to '1'. This procedure will be repeated bit by bit and then the validity of the updated codeword \mathbf{r} will be checked by applying the equation: $\mathbf{s} = \mathbf{H} * \mathbf{z}^{\mathbf{T}}$ (where \mathbf{z} is the corrected codeword). If there is any element in the syndrome $\mathbf{s} \neq$ '0', the whole algorithm will be repeated from the second step.

Detailed procedures of the algorithm can be viewed in the following example.

Example 2.4.3 ————

Same as example 2.4.2, the codeword $\mathbf{c} = [0\ 0\ 1\ 0\ 1\ 1]$ was received as $\mathbf{r} = [1\ 0\ 1\ 0\ 1\ 1]$ after traveling through the same BSC (crossover probability $\mathbf{p} = 0.2$).

For this codeword, the log likelihood of ' $\mathbf{r}_i = 1$ ' is log (0.2/0.8) = -1.3863 and the log likelihood of ' $\mathbf{r}_i = 0$ ' is log (0.8/0.2) = 1.3863.

Therefore, the vector \mathbf{r} will be firstly refreshed as:

$$\mathbf{r} = [-1.3863, 1.3863, -1.3863, 1.3863, -1.3863, -1.3863].$$

And so, the matrix M which has the same size of H becomes to:

$$\mathbf{M} = \begin{bmatrix} -1.3863 & 1.3863 & 0 & 1.3863 & 0 & 0 \\ 0 & 1.3863 & -1.3863 & 0 & -1.3863 & 0 \\ -1.3863 & 0 & 0 & 0 & -1.3863 & -1.3863 \\ 0 & 0 & -1.3863 & 1.3863 & 0 & -1.3863 \end{bmatrix}$$

Therefore, the message sent from the bit node j to the check node i can be represented as $M_{j,\,i}$, which is also the log formed current estimated probability of the codeword's bit i = '1' according to check j.

Hence, the extrinsic message from check node j to bit node i, or the LLR of the probability that bit i causes parity-check j to be satisfied is:

$$E_{j,i} = \log \left(\frac{1 + \prod_{i' \in B_j, i' \neq i} \tanh(M_{j,i'}/2)}{1 - \prod_{i' \in B_j, i' \neq i} \tanh(M_{j,i'}/2)} \right)$$

Where:

$$\tanh\left(\frac{1}{2}\log\left(\frac{1-sq1}{sq1}\right)\right) = 1 - 2sq1$$

And:

$$M_{\rm i, i'} \neq 0;$$

Since in this example:

$$B_1 = \{1, 2, 4\};$$
 $B_2 = \{2, 3, 5\};$ $B_3 = \{1, 5, 6\};$ $B_4 = \{3, 4, 6\};$

So, from B_1 :

$$E_{1,1} = \log \left(\frac{1 + \tanh(M_{1,2}/2) \tanh(M_{1,4}/2)}{1 - \tanh(M_{1,2}/2) \tanh(M_{1,4}/2)} \right)$$

$$= \log \left(\frac{1 + \tanh(1.3863/2) \tanh(1.3863/2)}{1 - \tanh(1.3863/2) \tanh(1.3863/2)} \right)$$

$$= \log \left(\frac{1 + 0.6*0.6}{1 - 0.6*0.6} \right) = 0.7538.$$

$$E_{1,2} = \log \left(\frac{1 + \tanh(M_{1,1}/2) \tanh(M_{1,4}/2)}{1 - \tanh(M_{1,1}/2) \tanh(M_{1,4}/2)} \right)$$

$$= \log \left(\frac{1 + \tanh(-1.3863/2) \tanh(1.3863/2)}{1 - \tanh(-1.3863/2) \tanh(1.3863/2)} \right)$$

$$= \log \left(\frac{1 + -0.6*0.6}{1 - -0.6*0.6} \right) = -0.7538,$$

$$E_{1,4} = \log \left(\frac{1 + \tanh(M_{1,1}/2) \tanh(M_{1,2}/2)}{1 - \tanh(M_{1,1}/2) \tanh(M_{1,2}/2)} \right)$$

$$= \log \left(\frac{1 + \tanh(-1.3863/2) \tanh(1.3863/2)}{1 - \tanh(-1.3863/2) \tanh(1.3863/2)} \right)$$

$$= \log \left(\frac{1 + -0.6*0.6}{1 - -0.6*0.6} \right) = -0.7538.$$

Repeat the calculations for each sets of parity check equations, the extrinsic LLRs will be:

$$E = \left[\begin{array}{ccccc} 0.7538 & -0.7538 & 0 & -0.7538 & 0 & 0 \\ 0 & 0.7538 & -0.7538 & 0 & -0.7538 & 0 \\ 0.7538 & 0 & 0 & 0 & 0.7538 & 0.7538 \\ 0 & 0 & -0.7538 & 0.7538 & 0 & -0.7538 \end{array} \right]$$

So the sums of non-zero elements in the matrix E will be:

$$Sum_E = [1.5076 0 -1.5076 0 0]$$

Since the updated likelihood of each codeword bit: $L_i = \mathbf{r}_i + Sum_E(i)$, therefore:

$$\mathbf{r}_{i}$$
 [-1.3863 1.3863 -1.3863 -1.3863 -1.3863]

+
$$Sum_E$$
 [1.5076 0 -1.5076 0 0 0]

L_i [0.1213 1.3863 -2.8938 1.3863 -1.3863 -1.3863]

After applying the hard decision on received bits based on the sign of Li, the corrected codeword will be: $\mathbf{z} = \begin{bmatrix} 0 & 0 & 1 & 0 & 1 & 1 \end{bmatrix}$.

And the syndrome **s** will be:

$$\mathbf{s} = \mathbf{H}^* \mathbf{z}^{\mathrm{T}} = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 1 \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

Therefore, the codeword **z** is valid.

2.4.4 Mackay and Neal's Decoding

In the year 1996, Doctor Mackay and Neal published a reinvented Gallager's Decoding algorithm (MacKay and Neal, 1996), which is called MN decoding algorithm. In this algorithm, the likelihoods of original bit-values were utilized to provide the hard decision for correcting the bit-values. However, rather than cumulative addition and cumulative multiplication used in the Sum-Product algorithm, only cumulative multiplication was involved in the algorithm. Furthermore, the signal to noise ratio (SNR) of AWGN channel was covered in the decoding process so that the error detecting and correcting processes could perform more accurate and faster. Brief introduction of the decoding process is shown in the following paragraphs.

For a received encoded codeword which has been interfered by an AWGN channel with the variance $\sigma^2 = 1$, the corresponding SNR can always be represented as:

$$SNR = \frac{E_b}{N_0} = \frac{a^2}{2R}$$

(Where ' $\pm \alpha$ ' is the binary input of the noise signal, and R is the code rate of the transmitted codeword.). So, if the SNR for a 1/2 rate 16200-length (DVB-S2 standard) codeword is known,

the value of ' α ' is exactly the root-value of SNR, that is $\alpha = SNR^{1/2}$. Therefore, the initial likelihood for the received bit $\mathbf{r}_n = 1$ can be represented as:

$$f_n^1 = 1/(1 + \exp(-2 \cdot \alpha \cdot \mathbf{r}_n));$$

where $n \in (1: 16200)$.

Since each bit-value is either '1' or '0', the initial likelihood of $\mathbf{r}_n = 0$ is:

$$f_n^0 = 1 - f_n^1$$
.

So for a 16200-length codeword, the length of the two vectors f^0 and f^1 should both equal to 16200. Once these two vectors have been cosntructed, the values of each pair of initial likelihoods will be assigned to the associated nonzero positions in the two 2D likelihood arrays Q^0_{mn} and Q^1_{mn} respectively, where Q^0_{mn} and Q^1_{mn} are in the same size of the parity check matrix \mathbf{H} for the received codeword \mathbf{r} , and \mathbf{m} is the number of checks while \mathbf{n} is the number of bits. That is Q^0_{mn} actually means: the probability of parity-check \mathbf{m} being satisfied when bit $\mathbf{r}_{\mathbf{n}} = 0$. Until now, the initialization step is finished and the horizontal step will begin.

In the horizontal step, the difference between each pair of Q^0_{mn} and Q^1_{mn} is calculated in advance and the results will be saved in the matrix δQ ($\delta Q_{mn} = Q^0_{mn} - Q^1_{mn}$). After that, for each bit \mathbf{r}_n , its likelihood difference δQ_{mn} will be updated according to the equation:

$$\delta Q_{mn} = \prod_{n' \in N(m), n' \neq n} \delta Q_{mn'}$$
 where $N(m) = \{n : H_{mn} = 1\}$

Which means that the value of δQ_{mn} is now the product of other values δQ_{mn} , which also participate in the same parity check equation **m** (Figure 2.4.4). Hence, the temporary probabilities R^0_{mn} and R^1_{mn} from horizontal step can be calculated as:

$$R_{\text{mn}}^0 = 0.5(1 + \delta Q_{mn})$$
 and $R_{\text{mn}}^1 = 0.5(1 - \delta Q_{mn}) = 1 - R_{\text{mn}}^0$

These temporary probability arrays will be used in the following vertical step.

As to the vertical step, the product of each set of checks \mathbf{m} in which the same bit \mathbf{n} participates will be firstly calculated (Figure 2.4.4). Eventually, the pseudo-posterior probabilities q_n^0 and q_n^1 can be calculated as:

$$q_n^{\scriptscriptstyle 0} = \int_n^{\scriptscriptstyle 0} \prod_{m \in M(n)} R_{mn}^{\scriptscriptstyle 0} \qquad q_n^{\scriptscriptstyle I} = \int_n^{\scriptscriptstyle I} \prod_{m \in M(n)} R_{mn}^{\scriptscriptstyle I}$$

where $M(n) \equiv \{m : H_{mn} = 1\}$ and equivalent to the set of checks in which the bit **n** participates. Therefore, each bit-value of the received codeword **r** is able to be updated according to the probabilities q_n^0 and q_n^1 . That is, if q_n^0 is greater than q_n^1 , the bit value of **r**_n will be set to '0'; Otherwise, **r**_n = '1'.

However, if the corrected message \mathbf{r} failed to pass the syndrome $\mathbf{s} = \mathbf{H}\mathbf{r}^{\mathbf{T}} = 0$, the probabilities Q^0_{mn} and Q^1_{mn} for each bit will be refreshed as:

$$Q_{mn}^{0} = f_{n}^{0} \prod_{m' \in M(n), m' \neq m} R_{m'n}^{0} \qquad Q_{mn}^{1} = f_{n}^{1} \prod_{m' \in M(n), m' \neq m} R_{m'n}^{1}$$

(Schematic of the operation can also be seen in figure 2.4.4).

And then the whole decoding process will repeat starting from horizontal step until the syndrome $\mathbf{s} = 0$ is satisfied.

Obviously, the Mackay and Neal's Decoding algorithm includes more cumulative multiplication operations than the Sum-Product Decoding method. On the C programming basis, implementing the cumulative multiplication operation is undoubtedly time-consuming. However, since the operation can be simplified to module-2 addition in this project, and the Sum-Product decoder has already been implemented by the ANU graduated student Mr. Sang Ik Park, the Mackay and Neal's Decoding algorithm is finally chosen as the decoding algorithm for this project.

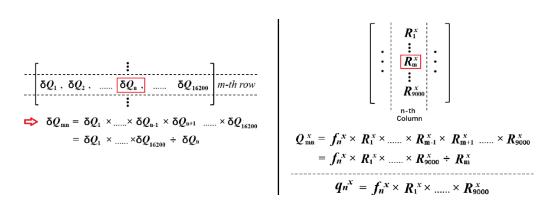

Figure 2.4.4: Schematic of the cumulative operations

3. Methodology

3.1 Attempt of Implementing New Encoder

As it has been mentioned in section 2.3, the DVB-S2 standard encoder is still in use for the associated models. The practical performance of the encoder has shown that the process for encoding a 7200-length message codeword takes no more than 20ms (Figure 3.0). This impressive speed ensures that the time interval between sending out two adjacent message codewords will not be aware of the users who are enjoying the audio-visual experience.

```
CLocks per sec = 1000000
BPSK_encoding - 15 (ms) elapsed.
Number of iterations, sim = 1 max_sim = 1
```

Figure 3.0: Practical Performance of the DVB-S2 Standard Encoder

However, this encoder is still dependent on the generator matrix G. In order to seek for the feasibility of directly encoding a message from the parity check matrix H, the algorithm – Low-Complexity Encoding of LDPC Codes (Hanghang Qi and Norbert Goertz, unknown) – was first-tentatively implemented in C programming, $y = \{y_1, y_2, ..., y_k\}$

According to Sarah Johnson's paper (Sarah Johnson, 2006), this particular encoding algorithm only using row and column permutations and back substitution to reform a randomly generated sparse parity check matrix **H** so that it could be shifted into systematic approximate lower triangular (SALT) form (Figure 3.1.1), and be utilized to generate parity check bits directly.

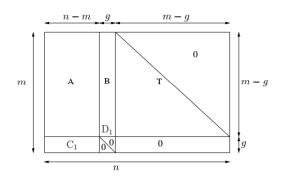

Figure 3.1.1: Parity Check Matrix H in SALT Form

By reviewing the paper of MacKay and Neal (MacKay and Neal, 1996), it can be noticed that the parity check matrix for the MN Decoder is suggested to be constructed by applying the construction 2A. That is in the **m** x **n** sized parity check matrix **H** (9000 x 16200 in this project), the first **m**/2 columns should be designated as weight 2 columns with zero overlaps between any pair of columns. That is, for each column ranging from index 1 to 4500, the number of nonzero elements should be '2' and the inner product for any two columns should be '0' (Figure 3.1.2). As to the remaining columns, three nonzero elements will be assigned to random locations with the inner product of any two columns is not greater than '1' (Figure 3.1.3).

Column (Column 2)^T

$$\begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} \times [0101] = 0$$

Figure 3.1.2: Example of the First 4500 Columns in H (Construct 2A)

Column4501 (Column4502)^T

$$\begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ 1 \end{bmatrix} \times \begin{bmatrix} 0 & 1 & 0 & 1 & 1 \end{bmatrix} = 1$$

Figure 3.1.3: Example of the Remaining Columns in H (Construct 2A)

In order to achieve these special requirements, there are 2 nonzero values '1' which were allocated in the rows 2i and 2i-1, where i is the index of the current column being operated on. This could ensure that there is only 1 nonzero element in each row of the first 4500 columns (Figure 3.1.4). After that, the row indexes were randomly rearranged so that the randomness can be guaranteed as well. The simplified code is shown as follow.

18

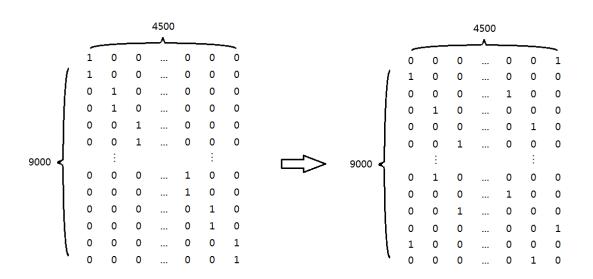

Figure 3.1.4: Partial Result of Construction 2A

In addition, the swap function (Appendix C) was achieved by using the *pointer* and the operation '^' so that the temporary variable used to assist the values' interchange in the traditional method can be abandoned. As a result, the memory resource is able to be saved for other operations.

Ideally, the remaining columns could be constructed by applying the above methods. However, since there would be 16200 - 4500 = 11700 columns in the second part of the matrix

H, if the inner product between any 2 columns is not greater than 1, there should be at least 11700 * (3-1) = 23400 rows in the whole matrix. That is, the predicted result of this particular method conflicts with the initial size of parity check matrix **H** (9000 * 16200). Therefore, the integrated algorithm was proven unachievable.

Nevertheless, the Low-Complexity encoding algorithm also includes the row and column permutations. So, as long as the sparseness of the matrix \mathbf{H} is satisfied, the matrix is still able to be constructed by permutations. Hence, the total number of nonzero elements were firstly calculated based on the construction method 2A, which is $4500 \times 2 + 11700 \times 3 = 44100$. Secondly, these nonzero binary numbers ('1's) were randomly allocated in the whole parity matrix \mathbf{H} , which had been reset to an all '0' matrix. Since the size of matrix \mathbf{H} is 145,800,000 (9000 * 16200), the sparse rate of the matrix is 44100 / 145,800,000 = 0.03%. This proved that the Low-Complexity encoding algorithm is suitable for this project.

In order to reform the parity check matrix **H** to the SALT form (figure 3.1.1), the first step should be applying rows and columns permutation so that the approximate lower triangular (ALT) form (Figure 3.1.5) can be obtained for the following back substitution.

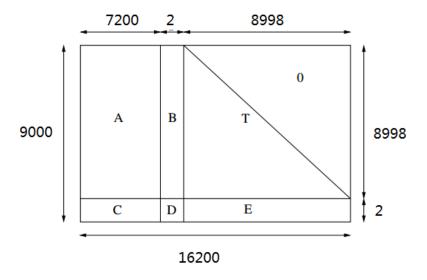

Figure 3.1.5: Parity Check Matrix H in ALT Form

As it has been mentioned in the previous slide, the columns ranging from 4501 to 16200 are weight 3 columns. Therefore, once the ALT formed matrix **H** has been generated, there should be 2 rows at the bottom of the matrix. As it can be shown in figure 3.1.5, the whole

matrix **H** was separated into 6 sub-matrices. Furthermore, the permutation operations are applied to reallocate the nonzero elements to the diagonal from the top-left corner to the bottom-right corner of the sub-matrix 'T', and then assign the rest nonzero elements to the locations except those which are above the diagonal. The method for this operation is: Firstly, finding out the row which has a '1' in the column 7203 and smaller number of '1's in the remaining columns; Then, reallocate the entire row to the first row while put the original first row to the bottom of the matrix; After that, the columns which contain '1' in the first row are interchanged with the columns which contain '0' and located in the areas 'AC' and 'BD'; Next, a row which contains a '1' in column 7204 is reallocated to the second row; Meanwhile, the original second row is moved to the bottom of the matrix; Similarly, columns which have a '1' in this row will be permuted to the areas 'AC' and 'BD'; Repeat the procedures for the rest elements in 'T' until the ALT formed matrix **H** is obtained.

Undoubtedly, the operation of rows and columns permutation was the stumbling block of this algorithm and it will sharply slow down the simulation speed of the encoder. Hence, an alternative method was figured out and implemented to construct the ALT formed matrix **H**.

In the initialization stage, all the elements in the matrix **H** were firstly reset to '0'. Then 8998 binary values '1' were assigned to the diagonal elements in 'T'. Meanwhile, the remaining 35102 '1's were randomly assigned to the elements in the area 'A', 'B', 'C', 'D', 'E' and the elements below the diagonal of sub-matrix 'T'. Hence, the complicated and time-consuming operations of rows and columns permutation have finally been replaced. Procedures can be represented in the following figure.

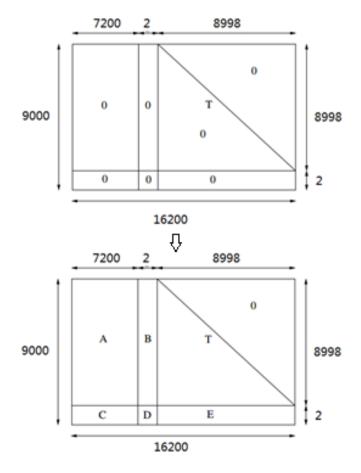

Figure 3.1.6: Alternative Algorithm to Construct ALT Formed Matrix H

After that, the sub-matrices 'C' and 'D' should be updated based on the equations:

$$C = -ET^{-1}A + C, \qquad D = -ET^{-1}B + D.$$

So, the following task for this algorithm is to figure out the way of obtaining the transpose matrix 'T-1'. C code for obtaining the transpose matrix can be found in Appendix D. The procedures of this function can be summarized as:

• Find out the matrix of mirrors

The matrix 'T' is in the size of 8998 x 8998. Therefore, for each element T[i][j] in the matrix, the whole matrix excludes the elements in the *i*-th row and *j*-th column (that is 'T_m' is in the size of 8997 x 8997) was firstly transferred to the *determinant* function.

• Find out the determinant

Firstly, calculate the results from the equation determinant = ad-bc (where the paired elements 'a' & 'b' and 'c' & 'd' share the same row index accordingly and the paired

elements 'a' & 'c' and 'b' & 'd' share the same column index respectively) and save the sum of the results in the determinants matrix ' T_d ' which has the same size of matrix 'T'.

Secondly, assign positive signs '+' and negative signs '-' to the elements in ' T_d ' so that in each pair of adjacent elements, the initial sign '+/-' of one element will remain unchanged while another's will be shifted inversely.

Finally, for each i and j, calculate $T[i][j] * T_d[i][j]$ and sum these results up to obtain the *determinant* for the matrix 'T'.

• Transpose matrix

For the elements in the matrix ' T_d ' obtained from above procedure, swap their positions over the diagonal so that the *adjugate* matrix T_a can be obtained. Then multiply each element in ' T_d ' by 1/determinant. Thus, the transpose matrix ' T^{-1} ' is worked out.

Obviously, this function is extremely complicated. Furthermore, hierarchical *for*-loops (inner *for*-loops within outer *for*-loops) were overused in the code, which directly caused the low speed of the encoder version 1. Surprisingly, it was found out that the resulted matrix 'T' was exactly the same as the matrix 'T' if the negative sign '-' can be ignored. The reason why is that since the values of the elements in matrix 'T' is either '1' or '0', the results from the calculation shown in the previous slide will consequently be binary number '-1', '0' or '1'. Additionally, in the following calculation procedures, only the absolute values of the elements in 'T-1' will be used to acquire the parity check bits. In other words, the matrix 'T' can be directly utilized for calculating the parity check bits. Therefore, the *inverse matrix* function was finally considered as unnecessary and has not been used in this project.

Once the transpose matrix T⁻¹ (which was replaced by matrix 'T' in practice) is obtained, the functions *matrix multiplication* (Appendix E) and *matrix addition* (Appendix F) should be applied to find out the resulted matrix 'ET', 'ETA' & 'ETB' and updated 'C' & 'D' gradually.

In the following paragraphs, the equation: C = -ETA + C will be demonstrated to describe the these functions.

From figure 3.1.6, the size of 'E' should be 2 x 8998 and the size of 'T' is supposed to be 8998 x 8998. Therefore, the numbers of rows and columns in 'E' were initialized to r1 = 2 and c1 = 8998 correspondingly; And since the matrix multiplication is achievable only if the number of columns in the first matrix ('E') equals to the number of rows in the second matrix 'T', so the parameters of matrix 'T' were set to r2 = c1 = 8998 and c2 = 8998 accordingly. So, for each element in the matrix 'ET', its value should be the product of each pair of E [i][p] and T[[p][j], where $i \in (1:2)$, $p \in (1:8998)$, and $j \in (1:8998)$. Since the elements in matrix 'ET' should always be '1' or '0' at the binary level, the systematic function '%' was utilized to convert the decimal results to binary values. Hence, by applying the for-loops hierarchically, the matrix 'ET' with the size of 2 x 8998 can be obtained by the following simplified code.

Similarly, the parameters were set to r1 = 2, c1 = 7200, r2 = c1 = 7200, c2 = 8998 to obtain the 2 x 8998 sized matrix 'ETA' and the inversely sighed 'NETA' (- $ET^{-1}A$).

for i = 1: $r1 \, do$

```
\label{eq:for} \begin{aligned} \textit{for } j = 1 \colon c2 \, \textit{do} \\ & \textit{for } p = 1 \colon c1 \, \textit{do} \\ & ETA[i][j] += ET \, [i][p] * A[p][j]; \\ & NETA[i][j] = -(ETA[i][j] \% \, 2); \\ & \textit{end for} \\ & \textit{end for} \\ \end{aligned}
```

Once the matrix 'NETA' was obtained, the *matrix addition* function is called to calculate the sum of the matrix 'NETA' and original 'C'. It is worth mention that since the matrix addition operation requires that the two matrices should be exactly in the same size, only one pair of parameters, which corresponds to the number of rows and number of columns respectively, are necessary to be set. Hence, the parameter r = 2 and c = 8998 were set as the input variables to the function.

```
for \ i = 1 : r \ do for \ j = 1 : c \ do C[i][j] = NETA \ [i][j] + C[i][j]; C[i][j] = C[i][j] \% \ 2; end \ for end \ for
```

Until now, the updated sub-matrices 'C' and 'D' were worked out. After resetting all the elements in the sub-matrix 'E' to '0', the parity check bits are able to be figured out. Before proceeding to the following sections, some correlated concepts are necessary to be introduced in advance.

As it has been mentioned in section 2, the encoded codeword \mathbf{c} actually includes two sub-vectors. That is, for a 16200-length codeword \mathbf{c} in this project, the first 7200 bits are exactly the same as the bits in the original message \mathbf{u} and the remaining 9000 bits belong to the parity check vector \mathbf{p} . So, the form of \mathbf{c} can be represented as $\mathbf{c} = \{\mathbf{u}, \mathbf{p}\}$. However, by applying the algorithm in this section, the parity check vector \mathbf{p} is partially obtained from two equations:

$$\mathbf{p_1} = D^{-1}C\mathbf{u}, \quad \mathbf{p_2} = -T^{-1}(A\mathbf{u} + B\mathbf{p_1})$$

Therefore, the encoded codeword \mathbf{c} should be represented as $\mathbf{c} = \{\mathbf{u}, \mathbf{p}_1, \mathbf{p}_2\}$. So, after applying the previously introduced functions and procedures, the original message \mathbf{u} is finally encoded to the codeword \mathbf{c} .

Ideally, this encoding algorithm should be able to encode a message which has either a systematic form of parity check matrix or a non-systematic form of parity check matrix. Although this requirement has been satisfied, the simulation result in C programming showed that the encoding time of this algorithm could take more than 5 minutes until complete. This is extremely terrible by comparison to the DVB-S2 standard encoder's performance (Figure 3.0). Therefore, improvements were made again to reduce the simulation time.

After doing some research works, it is noticed that the parity matrix for the DVB-S2 model should be in the systematic form already. That is the matrix \mathbf{H} consists of two sections, which are the matrix \mathbf{A} in the size of 9000 x 7200 followed by a 9000 x 9000 sized identity matrix \mathbf{I} . Hence the whole procedures in this section were further simplified as:

- Allocate 9000 binary values '1' into the elements which locate in the diagonal of the sub-matrix 'T'. Then randomly assign the remaining 35100 '1's to the elements in 'A'.
- Since there was no gap 'g' in the systematic-formed parity check matrix \mathbf{H} , the submatrices 'B', 'C' and 'D' are no longer existing in this algorithm. Hence, the parity check vector \mathbf{p} was directly calculated from the equation: $\mathbf{p} = T(A\mathbf{u})$.

• After combining with the initial message bits, the encoded codeword \mathbf{c} was obtained as $\mathbf{c} = \{\mathbf{u}, \mathbf{p}\}.$

This encoder was named as *Encoder Version 1* (Appendix G). Simulation result has shown that the performance of the encoder performs significantly faster than the encoder shown in previous slides. The encoding time for a 7200 length codeword **u** takes around 2 seconds (Figure 3.1.7) to complete, which is much faster than 5 minutes of the previous version.

```
CLocks per sec = 1000000
Current simulation = 1
ret = 1
Encoding 2122 (ms) elapsed.
```

Figure 3.1.7: Simulation Result of the Encoder Version 1

However, this encoding speed is more than 100 times slower than the DVB-S2 standard encoder (Figure 3.0). After reviewing Sang's code (Appendix H), the reason was figured out. That is, unlike other types of software which were designed for matrix associated calculation, such as MATLAB, C programming requires more memory resources to operate the similar calculation. Therefore, generating a 2D matrix in C programming and apply calculations on it are not as convenient as it was assumed. However, convert the matrix into 1D vectors – just like the method applied in Sang's code – would be more feasible in C environment. Thus, the DVB-S2 standard encoder which was implemented by Mr. Sang Ik Park (Appendix H) was finally used for this project.

3.2 In-depth understanding on Sang's Code

In order to test whether the decoder is working properly, the DVB-S2 encoder and the AWGN signal generator were used to create the initial message bits and the interfered encoded codeword bits. Although the DVB-S2 encoder and the AWGN signals generator were implemented in C by Mr. Sang Ik Park, it is still necessary to introduce the method of achieving

these implementations in advance so that the implementation of the decoder will not become sophisticated.

3.2.1 Gaussian Random Bit Generator

The function *Gaussian Random Bit Generator* was used to create the original message bits and the noise bits. Since the simulated noise signal in this project is the frequently used channel estimation method – the AWGN channel – which should have the additive noise of variance $\sigma^2 = 1$, so, the random bit generated from the function should range from '-1' to '1'.

In this function (shown in Appendix I), two random values ranging from 0 to 32767 are firstly generated by using the systematic function rand(). After dividing these two values by 32767 ($RAND_MAX$) and doubling the results, these two values will be narrowed to the range [0, 2]. After that, by subtracting '1' from these two results accordingly, the variables vI and v2 (range from -1 to 1), which participate in the variance check equation, will be generated.

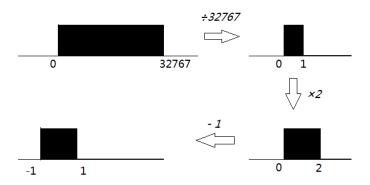

Figure 3.2.1: Procedures of Narrowing Random Generated Values

Therefore, the variance of the randomly generated values can be obtained as $s = vI^2 + v2^2$. Additionally, in order to ensure that the variance is ranging from '0' to '1', and to make sure the *double* typed values can be utilized properly, the *while* loop was applied to check whether the variance σ is greater than '0' and less than '1'. Meanwhile, the generated bit value will be reformed by the equation: $vI = vI * \sqrt{-2log(\sigma)/\sigma}$.

Although the variances of the noise signals have been satisfied, the randomly generated bit values are still not able to be directly utilized as the original message bits. The reason why is that in the signal processing domain, the bit values should be either the binary number '1' or

'0', while the generated bit values are actually decimals. Hence, the generated values are necessary to be converted to binary numbers accordingly by using the combination of *for-loop* and *if-loop*. That is if the result is greater than '0', then the bit will be set to the binary number '1'; otherwise, it will be set to the binary number '0'. This method is exactly the same as the *hard decision* method which was used in the decoder. The detailed introduction will be demonstrated in the following sections.

As it has been mentioned in the previous paragraph, the additive noise of variance $\sigma^2=1$ has already been satisfied as long as the noise signals were generated by the function. However, this noise signal is not able to be monitored for performance analysis. In other words, the signal to noise ratio (SNR) is supposed to be set before the simulation and utilized to control the noise level. Hence, extra procedures were applied on regulating the generated noise signal.

Firstly, the power of undisturbed signal bits was obtained by cumulatively summing up the values $\mathbf{c}[j]^2$, where j is the index of the encoded message bit ranging from 1 to 16200 and \mathbf{c} is the encoded message. Meanwhile, the noise's power was also acquired by cumulatively calculating the sum of the generated noise bits. Therefore, the SNR of the raw AWGN signal was calculated by:

$$SNR_raw = Spower / Npower = Sum(Signal_bit)^2 / Sum(Noise_bit)^2$$

Secondly, the pre-set SNR_{dB} was converted to the ratio form by applying:

$$SNR_{input} = 10^{-SNR_{dB}/10}$$

Finally, the regulated noise signal bits and the final SNR for the encoded message were updated by:

Noise_bit = Noise_bit *
$$\sqrt{SNR_raw}$$
 * $\sqrt{SNR_{input}}$
 $SNR = Sum(Signal_bit)^2 / Sum(Noise_bit)^2$

And the bits of the encoded message **c** went through the AWGN channel can be represented as:

or equivalently:

3.2.2 Method for Eliminating Zero Elements

Ideally, all the calculating operations should be applied on the 2D matrices. However, performing calculation procedures to all the elements in a large sized matrix, such as the 9000 x 16200 sized parity check matrix **H** in this project, costs a host of memory resources and will consequently reduce the speed of decoding. Considering that the parity check matrix in this project is a sparse matrix, which means the quantity of nonzero elements is relatively small by comparison to the total number of elements in **H**, and only nonzero elements are of interest in the decoding process, therefore, if there is a way to preserve the nonzero elements only while eliminating all the zero elements, the decoding process will be accelerated. Consequently, the creative approach introduced in Sang's code has been used in this project. The detailed introduction is shown in the follow paragraphs while the introduced index vectors of nonzero elements in the parity check matrix for this project can be found in Appendix B.

In a parity check matrix **H**, each element always has a column index and a row index. So, the value of an particular element can be represented as: **H**[row_index][column_index]. In order to eliminate the '0's in the matrix **H** (**m** x **n**), the row indexes and the column indexes of the nonzero elements in the first row of **H** are firstly stored in a row index vector and a column index vector respectively, and then the indexes of the nonzero elements in the second row of **H** are recorded by using another pair of vectors accordingly. After repeating the procedure until the reaches the last element in **H**, there will be **m** sets of row index vectors and **n** sets of column index vectors. After that, all the row index vectors and column index vectors are transferred orderly into a row-wise row index vector and a row-wise column index vector respectively. Hence, the length of the row-wise row index vector and row-wise column index vector will both equal to the number of nonzero elements in the parity check matrix **H**. Thus, the nonzero elements are able to be preserved. The workflow diagram can be seen in the following example.

Given that:

$$H = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix}$$
 row index

So, the positions of nonzero elements ('1') can be represented as:

Position of '1's =
$$\begin{bmatrix} (1,1) & (1,2) & - & (1,4) & - & - \\ - & (2,2) & (2,3) & - & (2,5) & - \\ (3,1) & - & - & (3,5) & (3,6) \\ - & - & (4,3) & - & (4,5) & (4,6) \end{bmatrix}$$

Therefore, the row index vector for the first row is: $\{1, 1, 1\}$;

And the row index vectors for the remaining rows are: {2, 2, 2}, {3, 3, 3} and {4, 4, 4} Similarly, the column index vectors for the corresponding rows will be:

$$\{1, 2, 4\};$$
 $\{2, 3, 5\};$ $\{1, 5, 6\};$ $\{3, 5, 6\}$

Combining these vectors so that:

Row-wise row index vector
$$= \{1, 1, 1, 2, 2, 2, 3, 3, 3, 4, 4, 4\}$$

Row-wise column index vector = $\{1, 2, 4, 2, 3, 5, 1, 5, 6, 3, 5, 6\}$

However, in the decoding process, if two matrices are multiplied together, the elements in the i-th row of the first matrix and the elements in the i-th column of the second matrix should be multiplied with each other iteratively. Hence, the positions of nonzero elements in \mathbf{H} should also be represented in the column-wise form. And consequently, there will be a column-wise row index vector and a column-wise column index vector as well.

For the same parity check matrix **H** shown in example 3.1:

$$H = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix}$$
 row index

The positions of nonzero elements ('1') are:

Position of '1's =
$$\begin{bmatrix} (1,1) & (1,2) & - & (1,4) & - & - \\ - & (2,2) & (2,3) & - & (2,5) & - \\ (3,1) & - & - & (3,5) & (3,6) \\ - & - & (4,3) & - & (4,5) & (4,6) \end{bmatrix}$$

Now the row index vector for the nonzero elements in the first column is: {1, 3};

And the row index vectors for the nonzero elements in the remaining columns are:

$$\{1, 2\}; \{2, 4\}; \{1\}; \{2, 3, 4\}; \{3, 4\}.$$

Similarly, the column index vectors for the matrix will be:

$$\{1,1\}; \{2,2\}; \{3,3\}; \{4\}; \{5,5,5\}; \{6,6\}.$$

Combining this vectors so that:

Column-wise row index vector $= \{1, 3, 1, 2, 2, 4, 1, 2, 3, 4, 3, 4\}$

Column-wise column index vector = $\{1, 1, 2, 2, 3, 3, 4, 5, 5, 5, 6, 6\}$

3.3 Implementation of the MN Decoder

The implementation of the MN Decoder was set as the main task for the second half project period. As it has been demonstrated in section 2.4.4, the MN Decoder covers six main steps, which are *Interfered signal delivery*, *Initialization*, *Horizontal step*, *Vertical Step*, *Hard*

Decision and Validity Check. During each simulation, the received signal, which has been interfered, will be iteratively corrected and checked. Practical results have shown that the maximum iteration for each simulation is supposed to be set as 150 so that the randomly generated original message could be fully recovered. The workflow block diagram of the decoder is shown as follow, while the detailed flowchart can be found in Appendix J.

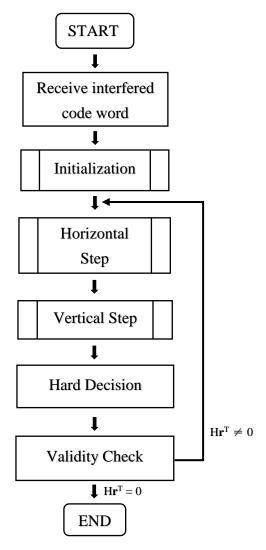

Figure 3.3: Workflow Block Diagram of the MN Decoder

Once the interfered message z was received, the decoder will firstly compute the likelihood of each bit based on the equations in the initialization step:

$$f_n^1 = 1/(1 + \exp(-2 \cdot \alpha \cdot \mathbf{z}_n))$$
 and $f_n^0 = 1 - f_n^1$.

Where $\alpha = \sqrt{SNR}$ in this project.

Hence, the vector *Column-wise column index* is used to iteratively assign the likelihood for each message bit to the nonzero elements in the same column of the vector-formed matrices Q^I and Q^0 . The simplified code can be shown as follow.

```
for i = 1: Number of nonzero elements do Q^{I}[i] = f^{I}[Column-wise\ column\ index[i]]; Q^{0}[i] = f^{0}[Column-wise\ column\ index[i]]; end for
```

Since the elements in the same column of matrix \mathbf{H} share the same column index, so, in the column-wise column index, there always be sets of continuous elements sharing the same column index value. That is, with the increase of i, the values of variable Column-wise column index[i] will periodically perform the same value. Hence, the variables $f^{I}[Column$ -wise column index[i]] and $f^{0}[Column$ -wise column index[i]] will assign sets of continuous same value to the vector-formed matrices $Q^{I}[i]$ and $Q^{0}[i]$ respectively. As a result, only the nonzero elements' likelihoods are saved in the vector-formed matrices Q^{I} and Q^{0} . Hence, these two vectors could be used to represent the likelihoods of nonzero elements in the entire matrix \mathbf{H} .

As to the horizontal step, the difference between each pair of $Q^0[i]$ and $Q^1[i]$ are calculated and stored in the vector-formed matrix dtQ, of which the length is the number of nonzero elements. According to section 2.4.4, the next step should be: for each element $dtQ_{mn}[i][j]$, computing the product of the other elements in the same row and assign the result back to $dtQ_{mn}[i][j]$. Alternatively, the product of the elements in the same row of dtQ_{mn} (including the element being operated on) was firstly computed and stored in an **m**-length vector by using a *for-loop*. After that, another *for-loop* was used to calculate the quotient of the row-product value and the value of the element which is being operated on. An example of this particular step is shown as follow.

Example 3.3.1 —

Ideally, for a random row [1, 2, 3, 4] in a 4*4 matrix, the elements of the three bits should be updated as:

$$Bit \ 1 = Bit \ 2 \times Bit \ 3 \times Bit \ 4 = 2 \times 3 \times 4 = 24;$$
 $Bit \ 2 = Bit \ 1 \times Bit \ 3 \times Bit \ 4 = 1 \times 3 \times 4 = 12;$

Bit
$$3 = Bit \ 1 \times Bit \ 2 \times Bit \ 4 = 1 * 2 * 4 = 8$$
; Bit $4 = Bit \ 1 \times Bit \ 2 \times Bit \ 3 = 1 * 2 * 3 = 6$;

By applying the alternative method, the product of bit values is firstly calculated as:

Row product =
$$1 * 2 * 3 * 4 = 24$$

Then the bit values can be updated as:

Bit
$$1 = Row \ product \ / \ Bit \ 1 = 24 \ / \ 1 = 24$$
; Bit $2 = Row \ product \ / \ Bit \ 2 = 24 \ / \ 2 = 12$;

Bit
$$3 = Row \ product \ / \ Bit \ 3 = 24 \ / \ 3 = 8$$
; Bit $4 = Row \ product \ / \ Bit \ 4 = 24 \ / \ 4 = 6$;

Similar to the initialization step, the vector Column-wise row index is utilized in the code to reduce the memory resource consumption. Meanwhile, the temporary probabilities R^0 and R^1 are also able to be computed. It is worth mention that the implementation of the alternative method shown in example 3.3.1 must be separated into two for-loops so that the product of the elements in each row can be fully computed and will not cause any error in the second procedure.

for i = 1: Number of nonzero elements **do**

Product dtQ[Column-wise row index[i]] = Product dtQ[Column-wise row index[i]]/dtQ[i];
end for

for i = 1: Number of nonzero elements **do**

 $Updated \ dtQ[i] = Product \ dtQ[Column-wise \ row \ index[i]] \ / \ dtQ[i];$

 $R0[i]=0.5*(1+Updated\ dtQ[i]);$

R1[i]=1-R0[i];

end for

Until now, the program has finished the initialization and horizontal step. Recall the equations in the vertical step shown in section 2.4.4:

$$q_{n}^{0} = f_{n}^{0} \prod_{m \in M(n)} R_{mn}^{0} \qquad q_{n}^{1} = f_{n}^{1} \prod_{m \in M(n)} R_{mn}^{1}$$
(1)

From equation (1) it can be found out that the pseudo-posterior probability q_n^0 of the bit $\mathbf{r}_n = 0$ equals to the product of the initial probability f_n^0 and the term $\prod_{m \in M(n)}^{n} R_{mn}^0$. Therefore, the term $\prod_{m \in M(n)}^{n} R_{mn}^0$ should be a vector which has the same size of the vector f_n^0 . In other words, the vector $\prod_{m \in M(n)}^{n} R_{mn}^0$ is an \mathbf{n} -length vector which consists of the products of the elements in the same columns of the matrix R^0 . Thus, the vector *Column-wise column index* is used in the following simplified code.

for i = 1: Number of nonzero elements **do**

 $Product \ R1[Column-wise\ column\ index[i]] = Product\ R1[Column-wise\ column\ index[i]] * R1[i];$ $Product\ R0[Column-wise\ column\ index[i]] = Product\ R0[Column-wise\ column\ index[i]] * R0[i];$ $end\ for$

$$for \ i = 1: 16200 \ do$$

$$q1[i] = f1[i] * Product \ R1[i];$$

$$q0[i] = f0[i] * Product \ R0[i];$$

end for

//where:
$$Product \ R1[i] = \prod_{m \in M(n)}^{n-1} n$$
 and: $Product \ R0[i] = \prod_{m \in M(n)}^{n-1} n$

Ideally, the sum of the two pseudo-posterior probabilities q_n^0 and q_n^1 for each bit \mathbf{r}_n should always equal to '1' ($p(\mathbf{r}_n=1)+p(\mathbf{r}_n=0)=1$). However, the practical results have shown that the generated result of $q_n^0+q_n^1$ may sometimes become a relatively small decimal which is less than '1'. Hence, a variable *sumq* is used to amplify the values q_n^0 and q_n^1 simultaneously so that their sum could be increased to '1'.

```
for i = 1: 16200 do
sumq = q1[i] + q0[i];
q1[i] = q1[i] / sumq;
q0[i] = q0[i] / sumq;
sumq = 0;
end for
```

Once the pseudo-posterior probabilities have been worked out, the hard decision will be applied to the update the bit value \mathbf{r}_n . That is, if q_n^I is greater than q_n^0 , the value of \mathbf{r}_n will become '1'; Otherwise, $\mathbf{r}_n =$ '0'. Once all the message bits \mathbf{r}_n is updated, the program will check whether the syndrome $\mathbf{s} = \mathbf{H} * \mathbf{r}$ is a sequence of '0's. This was easily achieved by calculating the sum of the elements in vector \mathbf{s} and check whether the result is a '0'.

As shown in section 2.4.4, the vector-formed pseudo-posterior probabilities $Q^{I}[n]$ and $Q^{0}[n]$ of bit \mathbf{r}_{n} , which were suggested by the check \mathbf{m} , should also be computed so that if the updated message failed to pass the validity check (sum(\mathbf{s}) \neq 0), these two probabilities will be sent back to the horizontal step.

$$Q_{mn}^{0} = f_{n}^{0} \prod_{m' \in M(n), m' \neq m} R_{m'n}^{0} \qquad Q_{mn}^{1} = f_{n}^{1} \prod_{m' \in M(n), m' \neq m} R_{m'n}^{1}$$
(2)

As it can be seen in equation (2), the calculating procedure looks similar to the procedure for computing q_n^0 and q_n^1 . However, in this procedure, the pseudo-posterior probability of the current bit, which is being operated on, is excluded in the cumulative multiplication operation. Since the terms $\prod_{m \in M(n)}^{R_{mn}^1}$ and $\prod_{m \in M(n)}^{R_{mn}^0}$ have already been worked out in the code shown in previous slide, the values $\prod_{m' \in M(n), m' \neq m}^{R_{m'n}^0}$ and $\prod_{m' \in M(n), m' \neq m}^{R_{m'n}^1}$ can be computed by applying the alternative method shown in example 3.3.1. Hence, the implementation of this equation can be achieved by the following simplified code.

```
for i=1: Number of nonzero elements do

product\ R1[i] = Product\ R1[Column-wise\ column\ index[i]]/R1[i];
product\ R0[i] = Product\ R0[Column-wise\ column\ index[i]]/R0[i];
Q1[i] = f1[Column-wise\ column\ index[i]] * product\ R1[i];
Q0[i] = f0[Column-wise\ column\ index[i]] * product\ R0[i];
end\ for
//where:\ product\ R1[i] = \prod_{m' \in M(n), m' \neq m} R_{m'n}^{l} \qquad and:\ product\ R0[i] = \prod_{m' \in M(n), m' \neq m} R_{m'n}^{l}
```

Similarly, for each pair of Q^I and Q^0 , their values should also be amplified simultaneously so that the sum of these two likelihood values equals to '1'.

```
for i = 1: Number of nonzero elements do sumQ = Q1[i] + Q0[i]; Q1[i] = Q1[i] / sumq; Q0[i] = Q0[i] / sumq; sumQ = 0; end for
```

Consequently, the equations shown in the Mackay and Neal's Decoding algorithm have been implemented in C programming. What's more, debugging results suggested that in order to reset all the bits in a vector (such as R^1 and R^0 , q^1 and q^0 and dtQ) to '0', the systematic function *memset* (vector's name, 0x00, size of vector) provides an instantaneous way to reset the entire vectors rather than set the elements to '0' bit by bit gradually by using a for-loop. In addition, since all the elements in the vectors which are used to preserve the product (such as product R^1 , product R^0 and product dtQ) should be initialized to '1' in each iteration (while-

loop) in the decoder section, the same sized vectors (all elements = '1') were firstly generated in the main function; Secondly, elements in these vectors were copied into the corresponding vectors by using the systematic function *memcpy* (*targeted vector's name, all '1's vector, size of vector*). Hence, the duration of decoding each 16200-length encoded message was increased by up to 20ms.

4. Results and Discussion

In order to compare the decoding performance of the Sum-Product Decoder and the MN Decoder, both of the C code constructed by Sang Ik Park (Appendix H) and the new decoder constructed in this project period (Appendix I) were running on the same laptop. The system of the laptop is Linux Ubuntu 16.04. Additionally, the values of the parameters: maximum simulation of the code and the maximum iteration for the decoding process were both set as 150 in the two C codes.

4.1 Performance on Bit Error Correction

One of the key measurements for assessing the practical performance of a decoder is the ability of bit error correction. This parameter is usually represented as bit error rate (BER) which equals to the number of error bits divided by the total number of message bits. Since this parameter is highly correlated with the input variable Signal to Noise Ratio (SNR), during the simulations, the variable SNR was equally assigned as 0.1dB to 10dB in both of the codes. Detailed performance of these two decoders can be seen in the following table.

Table 4.1: BER of the Decoded Message from the Decoders

SNR(dB)	Raw BER	BER (Sum-Product Decoder)	BER (MN Decoder)
0	0.1560	0.0000	0.0000
1	0.1296	0.0000	0.0000
2	0.1018	0.0000	0.0000
3	0.0810	0.0000	0.0000
4	0.0565	0.0000	0.0000
5	0.0386	0.0000	0.0000
6	0.0213	0.0000	0.0000
7	0.0116	0.0000	0.0000
8	0.0064	0.0000	0.0000
9	0.0026	0.0000	0.0000
10	0.0011	0.0000	0.0000

As shown in table 4.1, after going through the decoding process, the bit error rates can be reduced to '0.0000'. That is both of the Sum-Product Decoder and the MN Decoder are able to fully correct the error bits. Therefore, there is no difference on the accuracy of bit error correction.

4.2 Performance on Decoding Speed

Another key measurement of a decoder's practical performance is the decoding efficiency. That is how fast the decoding process could achieve. Similarly, the same set of SNR values were set as the input parameter for both of the decoders. Additionally, in order to enhance the accuracy of the data, the average decoding time calculated from totally 100 simulations was recorded as the result. Meanwhile, a *timer* was utilized to count the total time of the decoder to fully recovered a 16200-length received message. Hence, the average decoding time for each simulation was computed as *Average Decoding Time* = *Total Running Time* / *100 Simulations*.

Table 4.2: Average Decoding Time of the Decoders

SNR(dB)	Average decoding time (Sum-Product Decoder)	Average decoding time (MN Decoder)
0.1	339.06ms	110.78ms
1	80.48ms	24.24ms
2	49.80ms	16.24ms
3	38.08ms	12.27ms
4	28.47ms	9.71ms
5	26.14ms	9.38ms
6	20.22ms	8.59ms
7	16.82ms	7.42ms
8	13.75ms	7.05ms
9	10.77ms	6.07ms
10	8.17ms	5.79ms

As shown in the above table, with the increase of SNR, the average decoding time for both of the two decoders gradually decrease. The reason is that the higher SNR value is, the smaller the total number of error bits will be. As a consequence, fewer iterations will be required

in the decoders. However, the result shows that when the parameters were set as the same, the decoding speed of the MN Decoder is always faster than that of the Sum-Product Decoder in each simulation. To be more specific, even if the bit error rate is 0.0011 (table 4.1), which means almost zero message bits were wrongly transmitted, the Sum-Product Decoder still need to spend almost 10ms to decoding the message. In contrast, the MN Decoder needs only 5.79 ms to correct the small quantity of error bits. Additionally, when the SNR was set to 0.1dB (all the received bits differ from the transmitted bits), the MN Decoder requires 110.78ms to fully recover the entire message, which is three times shorter than that of the Sum-Product Decoder (339.06ms)

To sum up, the MN Decoder performs the same error correction accuracy as the Sum-Product Decoder. However, the decoding speed of the MN Decoder is obviously faster than that of the Sum-Product Decoder.

5. Conclusion and Future Development

In the project period, the basic knowledge of signal encoding and decoding have been suggested and researched. Additionally, two types of encoding algorithms (DVB-S2 standard encoding algorithm and the Low-Complex encoding algorithm) and four types of decoding algorithms (Erasure Decoding, Bit-Flipping Decoding, Sum-Product Decoding and the Mackay and Neal's Decoding algorithms) also contributed extraordinarily to the construction of the correlated knowledge foundation.

From the encoder implementation stage, it is finally found out that the Low-Complex Encoding algorithm is not suitable for the DVB-S2 model since the parity check matrix for the model is already in the systematic form, in which the rows and columns permutation process is not required.

By comparison to the practical performance of Sang's Sum-Product decoder, the MN Decoder performs the same decoding accuracy but a faster decoding speed. Therefore, it can be concluded that the decoding efficiency of the MN Decoder is higher than that of the Sum-Product decoder. The reason can be concluded as that the trigonometric and log operations used in the Sum-product decoding algorithm are not utilized in the MN decoding algorithm, which saved the memory resource for the remaining procedures. Hence, it is suggested that the currently used Sum-Product decoder in the DVB-S2 model can be replaced by the MN Decoder.

As to the future development, it is worth mention that although the decoding efficiency of the MN Decoder is higher than the Sum-Product decoder, the data rate of the decoding process can reach up to 1.2Mbps only, which is still not as high as 10Mbps. However, the data rate of the decoding process is not able to be further accelerated in the C programming domain. Therefore, it is highly recommended to implement this algorithm in Verilog hardware description language to seek for the opportunity of boosting the decoding data rate.

Appendix B: Indexes of nonzero elements in the paritycheck matrix H (9000 x 16200)

B1: Row-wised row index:

15, 15, 16, 16, 16, 16, 17, 17, 17, 17, 17, 17, 18, 18, 18, 18, 18, 19, 19, 19, 19, 20, 20, 20, 20, 20, 20, 21, 21, 21, 21, 21, 22, 22, 47, 47, 48, 48, 48, 48, 48, 49, 49, 49, 49, 49, 49, 50, 50, 50, 50, 50, 51, 51, 51, 51, 51, 51, 52, 52, 52, 52, 52, 52, 52, 52, 53, 60, 60, 60, 60, 60, 61, 61, 61, 61, 61, 61, 62, 62, 62, 62, 62, 62, 63, 63, 63, 63, 63, 63, 64, 64, 64, 64, 64, 64, 65, 65, 65, 65, 65, 78, 78, 78, 78, 79, 79, 79, 79, 80, 80, 80, 80, 80, 81, 81, 81, 81, 82, 82, 82, 82, 82, 83, 83, 83, 83, 83, 83, 84, 84, 84, 84, 84, 84, 85, 102, 102, 102, 103, 103, 103, 103, 103, 103, 104, 104, 104, 104, 105, 105, 105, 105, 105, 106, 106, 106, 106, 107, 107, 107, 126, 126, 126, 126, 126, 126, 127, 127, 127, 127, 127, 127, 127, 128, 128, 128, 128, 128, 128, 129, 129, 129, 129, 130, 130, 144, 145, 145, 145, 145, 145, 145, 146, 146, 146, 146, 146, 147, 147, 147, 147, 147, 147, 148, 148, 148, 148, 148, 149, 149, 181, 181, 182, 182, 182, 182, 182, 183, 183, 183, 183, 183, 183, 184, 184, 184, 184, 184, 185, 185, 185, 185, 185, 186, 186, 204, 204, 204, 205, 205, 205, 205, 205, 206, 206, 206, 206, 207, 207, 207, 207, 207, 208, 208, 208, 208, 208, 208, 209, 209, 213, 214, 214, 214, 214, 214, 214, 215, 215, 215, 215, 215, 216, 216, 216, 216, 217, 217, 217, 217, 217, 217, 218, 218, 218, 237, 237, 237, 237, 238, 238, 238, 238, 238, 238, 239, 239, 239, 239, 239, 240, 240, 240, 240, 240, 241, 241, 241, 292, 292, 293, 293, 293, 293, 293, 294, 294, 294, 294, 295, 295, 295, 295, 295, 295, 296, 296, 296, 296, 296, 297, 297, 297,
